Abstract—Cell sorting is a fundamental process that is involved in early embryo development, tumorigenesis and morphogenesis. The sorting of heterotypic cell populations is produced by a variety of inter-cellular actions, e.g. differential adhesion and motility. We recently developed a software system that simulates chemotaxis-based cell aggregation in 2D. The model implemented within the system includes a variety of physiological cell behaviors, such as chemical diffusion/detection, motility, proliferation, adhesion and life cycle stages. In this paper we extend the model to simulate heterotypic cell sorting. This paper provides an overview of the chemotaxis-based aggregation model and describes the parameters and processes utilized to simulate the sorting of two different cell populations based on chemotactic interactions.

I. INTRODUCTION

The differential sorting of heterotypic cells resulting in the enclosure of one cell grouping by another leads to the organization of tissues during morphogenic processes such as embryogenesis, organogenesis and tumorigenesis. Determining the processes that influence cell sorting should provide insights into cellular development and may lead to deeper understanding of the mechanisms behind more complicated biological processes, such as tumor development. The processes involved in embryonic cell sorting during early development include differences in chemotaxis, cellular adhesiveness, cell surface contractility and cell motility [11]. We present a computational model that captures many of these behaviors and is able to produce *in silico* characteristic heterotypic cell sorting outcomes for a two-cell-type population.

We recently developed a computational model that successfully captures some of the cell behaviors that play important roles in 2-D cell aggregation [3], [4], [5]. A virtual cell in our model is designed as an independent, discrete unit with a set of physiologically relevant parameters and actions. Each cell is defined by its size, location, chemoattractant receptors, rates of chemoattractant release and response, age, life cycle stage, quiescent period, proliferation rate and number of attached cells. All cells are capable of releasing and sensing a chemoattractant chemical, moving, attaching to other cells, dividing, aging and dying. We have demonstrated that the model is capable of recreating a 24-hour *in vitro* cell aggregation experiment. Here we have extended the computational model to simulate cell sorting

among two-cell populations with different chemotactic and motility properties.

Computational simulations were conducted to identify the parameters most influential to cell sorting and their associated values. The final desired outcome consists of a central core of Type 1 (blue) cells surrounded by a layer of Type 2 (red) cells (see Figure 3). Once this result was produced a parametric study was performed to highlight the influence of the most important cell parameter, the probability that a Type 2 cell will respond to the Type 1 chemoattractant.

II. OVERVIEW OF CHEMOTAXIS-BASED CELL AGGREGATION MODEL

Within our computational model a cell's life cycle and behaviors are implemented as a set of actions that is performed during each time step of a simulation. A single aggregation simulation is comprised of a series of time steps. The actions taken by a cell at each of these time steps in our original aggregation simulations are outlined in Figure 1. Newly proliferated cells remain in a quiescent state for a user-defined period where they temporarily cannot divide. A quiescent cell is either separating from its sister cell or it is "waking up", i.e. beginning to respond to chemoattractant gradients. Based on the chemical fields produced by nearby cells a gradient is calculated and the cell responds to it by moving in the gradient direction. If cells collide, they attach to each other. A cell's age is incremented at each time step. If the cell is apoptotic (i.e. unattached after a specific age), it probabilistically determines if it should die. If the state of the complete environment is to be saved for visualization purposes, the cell emits and stores its chemical field in the chemoattractant array. If in the *Active* stage, the cell probabilistically determines if it is time to divide. If it divides, its and its daughter cell's age are set to zero, and they enter the quiescent stage.

All *in-silico* experiments represented in this paper contains 200 Type 1 and 200 Type 2 cells. All virtual cells live on a $500 \times 433 \mu\text{m}$ grid representing a 2-D area of a Petri dish. Each cell has a radius of $6 \mu\text{m}$. Chemoattractants are secreted from the cell's surface symmetrically and diffuse radially. The concentration of chemoattractant initially secreted by a single cell at its surface is $C_0 \text{ molecules}/\mu\text{m}^2$ ($C_0 = 180$ in our experiments). We assume that a constant chemical

produce the desired result pictured in Figure 3 are listed in Table I. These values show that T_1 (blue) cells strongly respond to their own type of chemoattractant ($\lambda_1 = 20$), but do not respond at all to C_2 ($\lambda_2 = 0$). T_2 cells respond weakly to C_1 ($\lambda_2 = 1$), and their response to their own chemoattractant (C_2) is even weaker ($\lambda_2 = 0.1$). Since P_i is the probability that a cell will respond to chemoattractant concentration C_i , it can be seen that T_1 cells always respond to their own chemoattractant ($P_1 = 100\%$), and never

respond to C_2 ($P_2 = 0\%$). T_2 cells respond to their own chemoattractant 10% of the time. Initially T_2 cells respond to C_1 10% of the time, but after T_R their response rate ramps up to 100%, as defined by Equation 3.

As seen in Figure 2, the two cell populations are initially mixed. Since blue Type 1 cells strongly and always attract each other, they quickly form small aggregates, which then ultimately come together to form a single blue grouping. Red Type 2 cells move slower than blue cells and only respond to chemical gradients 10% of the time; thus producing a loosely packed “cloud” around the tightly packed blue Type 1 core (bottom left). After T_R as the Type 2 cells become more strongly attracted to Type 1 cells, the Type 2 cells then form a tightly packed layer around the Type 1 cells (bottom right).

We also studied the effect of varying the T_2 cells’ P_1 value on the structure of the final sorted cells. All P_i values were kept constant during these simulations. The results for $P_1 = 0, 0.1, 0.2$ and 1.0 are shown in Figure 4. When $P_1 = 0$ for Type 2 cells, they do not respond to C_1 . Their response to C_2 is also weak. So as blue cells aggregate quickly, the red cells only show minimal signs of aggregating amongst themselves. See Figure 4 top left. Setting $P_1 = 0.1$ produces a result similar to Figure 2 bottom left. Our experiments showed that an increase in P_1 from 0.1 to 0.2 significantly changes the cell sorting behavior. Once this parameter is over 0.1, T_2 cells aggregate more aggressively and begin to surround the T_1 cells. The T_2 cells’ behavior interferes with the aggregation of the T_1 cells, and the T_1 cells remain in separate groups rather than aggregating into a single large

Fig. 4. Modifying T_2 's probability of responding to chemoattractant C_1 . Results for $P_1 = 0, 0.1, 0.2$ and 1.0 . T_2 cells show little sign of aggregating when $P_1 = 0$ (top left). $P_1 = 0.1$ produces the same result as Figure 2 bottom left (top right). Increasing P_1 to 0.2 results in two smaller aggregates. Once the T_2 cells spread over the T_1 cells, the T_1 cells are prevented from aggregating further (bottom left). T_2 cells acts similar to T_1 cells and create an almost uniform distribution when $P_1 = 1$ (bottom right).

structure. See Figure 4 bottom left. A different sorting pattern is observed when the T_2 cells' $P_R = 100\%$. Since the T_2 cells follow the C_1 gradient all of the time they produce an aggregation behavior similar to the T_1 cells. Some sorting is evident since the blue Type 1 cells' speed is 20 times greater than the red Type 2 cells.

All simulations required approximately 1 CPU-hour of computation time on an Apple MacBook with Intel dual core 2.0 GHz processor and 1GB of RAM.

V. CONCLUSION

We have presented a 2-D chemotaxis-based computational model that successfully recreates heterotypic cell sorting behavior. By adjusting the parameters and processes of a chemotaxis-based cell aggregation model, we simulated the sorting of two cell populations with differing chemotactic and motility properties. Our *in silico* experiments identified the specific cell characteristics that affect chemotaxis-based cell sorting. The probability that a cell will follow a chemical gradient and the cell's speed in response to the gradient are the main factors that control cell sorting outcomes in our model.
